From Detection to Proficiency: The Coming Inversion of Academic AI Policy and a Framework for Assessing Student AI Utilization in Higher Education (2026–2035)

Sairam Kumar Reddy Veereddy
Independent Researcher, USA
July 2026

Abstract

Higher education's dominant institutional response to generative artificial intelligence has been detection: identifying and penalizing student use of large language models in assessed work. This paper argues that the detection paradigm is structurally unsustainable and will invert within a decade. Drawing on assessment theory, distributed cognition, and empirical evidence on AI-augmented knowledge work, I develop the case that by the early 2030s the central assessment question will shift from "did the student use AI?" to "how well did the student use AI?" I propose AI Utilization Proficiency (AUP) as an assessable construct comprising six dimensions—task decomposition, prompt construction, iterative refinement, critical verification, synthesis and attribution, and tool orchestration—and introduce Baseline Differential Analysis (BDA), an estimation method that infers utilization quality from submitted artifacts alone by comparing them against machine-generated minimal-effort baselines from the model the student reports using. Using scenario analysis across a 2026–2035 horizon, I trace three phases of transition: prohibition erosion, hybrid accommodation, and proficiency-centered assessment. The paper closes with implications for instructors, institutions, accreditors, and tool builders, and with the ethical constraints any utilization-scoring system must respect. The contribution is a conceptual and operational bridge between assessment theory and the emerging reality of AI-saturated knowledge work.

Keywords: generative artificial intelligence, assessment reform, academic integrity, prompt engineering, higher education, AI literacy

1. Introduction

Universities are fighting the last war. Since the public release of ChatGPT in late 2022, the modal institutional reaction to generative AI has been defensive: honor-code revisions, detector procurement, oral re-examinations, and a return to proctored, handwritten assessment (Cotton et al., 2024; Rudolph et al., 2023). The

implicit theory behind these measures is that unassisted cognitive performance is the thing worth certifying, and that AI assistance is noise to be filtered out of the signal.

That theory is quietly collapsing on two fronts. First, detection does not work well enough to bear institutional weight. Systematic evaluations of AI-text detectors find accuracy far below what disciplinary processes require, with false-positive rates that fall disproportionately on non-native English writers (Weber-Wulff et al., 2023; Liang et al., 2023). Second—and more fundamentally—the labor market that universities feed is moving in the opposite direction. Controlled studies of professional work show large productivity and quality gains when knowledge workers use large language models skillfully (Noy & Zhang, 2023; Dell'Acqua et al., 2023), and employer surveys now rank AI-related capability among the fastest-growing skill demands (World Economic Forum, 2023). A credential that certifies the ability to work *without* the dominant cognitive technology of the era is a credential of declining relevance.

This paper takes the next step that the assessment-reform literature has mostly gestured at but not operationalized. If working with AI is the competence that matters, then working with AI is the competence that must be graded. I argue that a measurable construct—AI Utilization Proficiency (AUP)—can be defined, taught, and assessed, and that within roughly a decade professors will routinely reward students for using *more* and *better* AI rather than less. The claim is deliberately stronger than the familiar "integrate AI thoughtfully" position: I contend that the direction of grading pressure itself will invert, such that shallow, single-prompt AI use is penalized not because it involved AI but because it involved AI *badly*.

The paper makes three contributions. Conceptually, it articulates the inversion thesis and grounds it in assessment theory and distributed cognition. Operationally, it specifies the AUP construct as a six-dimension framework with rubric anchors, and proposes Baseline Differential Analysis, a method for estimating utilization quality when only the final artifact and the identity of the model used are available—a realistic constraint, since process logs are easily curated and privacy-invasive to demand. Prospectively, it develops a three-phase scenario for 2026–2035 that institutions can use for planning rather than reaction.

2. The Detection Paradigm and Its Structural Failure

The detection paradigm treats generative AI as a contaminant in assessment. Its intellectual lineage runs through plagiarism management: text-matching services trained institutions to think of integrity as a screening problem, and AI detectors

were adopted as the natural extension (Perkins, 2023). The paradigm rests on three assumptions: that AI-generated text is reliably distinguishable from human text; that the distinction will remain stable as models improve; and that unaided performance is the valid target of certification.

Each assumption has failed or is failing. On distinguishability, the most comprehensive independent evaluation to date tested fourteen detection tools and concluded that none achieved the accuracy needed for high-stakes decisions, with performance degrading sharply under light paraphrasing (Weber-Wulff et al., 2023). Worse, the errors are not randomly distributed: detectors flag text by non-native English writers at several times the base rate, converting a technical limitation into an equity violation (Liang et al., 2023). On stability, detection is an adversarial game in which the generator side compounds capability with every model release while the detector side chases a moving target; there is no theoretical reason to expect the gap to close and considerable reason to expect it to widen. On validity, the assumption that unaided performance is what degrees should certify was always a convention rather than a law of nature. Assessment theorists have long argued that assessment should sample the performances that matter in the world beyond the classroom (Biggs, 1996; Sadler, 1989). When the world beyond the classroom is one in which professionals routinely think *with* machines, an assessment regime that forbids the machine measures a performance no one will ever again be asked to give.

The Australian tertiary regulator's expert report on assessment reform put the institutional implication plainly: the goal cannot be to outrun the technology, but to redesign assessment so that AI use is anticipated, structured, and evaluated (Lodge et al., 2023). UNESCO's (2023) global guidance points the same direction, urging human-centered integration over prohibition. What neither document yet supplies is a construct definition and scoring method for the thing to be evaluated. That gap is where this paper works.

3. Theoretical Foundations

3.1 Constructive Alignment and the Authenticity Requirement

Biggs's (1996) principle of constructive alignment holds that intended learning outcomes, learning activities, and assessment tasks must form a coherent system. Misalignment produces perverse incentives: students optimize for the assessment, not the outcome. The current situation is a textbook misalignment. Institutions declare outcomes such as “prepare graduates for contemporary professional practice” while assessing under conditions—no AI, closed book, time pressure—that contemporary professional practice never imposes. Realigning the system requires

that if AI-augmented performance is the outcome, AI-augmented performance must be the assessed activity, with quality criteria attached. Anderson and Krathwohl's (2001) revision of Bloom's taxonomy is instructive here: when a technology absorbs the lower strata of a cognitive hierarchy—remembering, summarizing, first-drafting—the assessable action necessarily migrates upward, toward evaluating, integrating, and creating with the technology's output as raw material.

3.2 Distributed Cognition and Cognitive Offloading

The theoretical warrant for grading human–AI performance as a unit, rather than insisting on isolating the human contribution, comes from distributed cognition. Hutchins (1995) demonstrated that real-world cognitive accomplishment—his canonical case was ship navigation—resides in systems of people and artifacts, not in individual skulls. Salomon (1993) drew the educational consequence: what matters pedagogically is the residue that working within an intelligent system leaves in the learner, and the learner's ability to orchestrate the system. Vygotsky's (1978) zone of proximal development, conceived for human tutors, extends naturally to machine collaborators: a student working with a capable model can operate beyond unaided reach, and the instructionally interesting variable is how skillfully they recruit that support. Cognitive load theory adds a caution and a design principle at once: offloading routine load is precisely what frees working memory for schema construction, but offloading the *germane* load—the struggle that produces learning—hollows the exercise out (Sweller, 1988). A proficiency construct must therefore reward offloading that amplifies thinking and penalize offloading that replaces it. This distinction, not the presence or absence of AI, is the pedagogically real boundary.

3.3 The Economics of Augmentation

Labor economics supplies the external pressure. Autor's (2015) analysis of automation showed that technology reprices rather than eliminates skill: tasks complementary to the machine appreciate, tasks substitutable by it depreciate. The generative-AI evidence now arriving fits that pattern with unusual clarity. Noy and Zhang (2023) found that ChatGPT access raised the productivity of professional writing tasks by roughly forty percent while compressing the skill gap between weaker and stronger writers. Dell’Acqua et al. (2023), studying hundreds of consultants at a global firm, found double-digit quality gains for AI-assisted work inside the technology's frontier of competence—but degraded performance when consultants trusted the model on tasks beyond that frontier. The managerial reading of that study is a curriculum in miniature: value accrues to workers who know where the frontier lies, how to decompose work across it, and how to verify what comes

back. These are precisely the abilities the AUP construct formalizes. Mollick (2024) calls the disposition “centaur” and “cyborg” work; the WEF (2023) forecasts put analytical thinking and AI/big-data capability at the top of employer demand. Universities can certify this competence deliberately or watch employers build their own certification around them.

4. The Inversion Thesis

The argument so far can be compressed into a syllogism. Assessment should target the performances that matter in graduates’ working lives (assessment theory). The performances that matter increasingly consist of skilled human–AI joint cognition (labor evidence). Skilled human–AI joint cognition varies enormously between individuals and is largely a learned capability (Dell’Acqua et al., 2023; Bearman & Ajjawi, 2023). Therefore assessment should target the skill of AI utilization itself.

The inversion thesis adds a prediction about institutional dynamics: grading pressure will not stop at neutrality (“AI permitted”) but will swing to active reward (“sophisticated AI use expected”). Three mechanisms drive the overshoot. First, differentiation: once AI use is universal, the only remaining variance for grades to track *is* quality of use—the lazy single-prompt submission and the deeply iterated, verified, synthesized submission must receive different marks or grading loses meaning. Second, pedagogical honesty: instructors who use these tools daily in their own research will find prohibition increasingly hypocritical and unenforceable, a pattern already visible in early adopter courses that assign AI use explicitly (Mollick & Mollick, 2023). Third, credential competition: the first institutions to certify AI proficiency credibly will capture employer preference, forcing followers. The same competitive ratchet that made computer literacy requirements universal in the 1990s operates here at higher speed.

It is worth being precise about what the thesis does not claim. It does not claim that unaided competence ceases to matter; verification of AI output is impossible without domain knowledge, so foundational assessment survives, likely in secured formats (Lodge et al., 2023). It does not claim uniform adoption across disciplines; clinical skills, laboratory technique, and proof-based mathematics retain large unaided cores. The claim is that for the broad middle of knowledge-work education—writing, analysis, design, research synthesis, software construction—the graded construct shifts from output-despite-AI to output-through-AI, with utilization quality as an explicit rubric dimension.

5. AI Utilization Proficiency: Construct and Measurement

5.1 Construct Definition

I define AI Utilization Proficiency as the demonstrated ability to recruit generative AI systems to produce work whose quality, depth, and reliability exceed both the student's unaided baseline and the model's unaided baseline. The definition is deliberately dyadic: proficiency is evidenced by the *gap* between what the human–AI system produced and what either party would produce alone. Drawing on the theoretical foundations above and on observed expert practice (Mollick, 2024; Dell'Acqua et al., 2023), I decompose the construct into six dimensions.

Task decomposition is the ability to partition a complex assignment into subtasks matched to the model's frontier—delegating what the machine does well, reserving what it does badly. *Prompt construction* covers the supply of context, constraints, examples, and role framing that separates a generic response from a targeted one. *Iterative refinement* is the willingness and skill to treat the first output as a draft: challenging, redirecting, and regenerating toward a goal the student holds and the model does not. *Critical verification* is the checking of claims, citations, and reasoning against independent sources—the dimension that most directly guards against the automation complacency documented by Dell'Acqua et al. (2023). *Synthesis and attribution* is the integration of machine output with the student's own knowledge, course material, and voice, together with honest disclosure of what was machine-assisted. *Tool orchestration* is the composition of multiple systems—retrieval, code execution, data tools, specialized models—into a workflow, the dimension that scales from single-chat use toward genuinely agentic practice.

Each dimension is describable at novice, competent, and expert anchor levels, which makes the construct rubric-ready in the ordinary sense familiar to any instructor (Sadler, 1989). A novice pastes the assignment question and submits the answer. A competent user supplies context, iterates a few times, and spot-checks facts. An expert decomposes the task, runs parallel approaches, interrogates weaknesses, verifies systematically, and produces work bearing an unmistakable individual signature. Instructors already intuit these differences; the framework merely names them so they can be taught and graded.

5.2 Baseline Differential Analysis

The measurement problem is that process evidence is unreliable. Chat transcripts can be curated before submission, screen recordings are invasive and burdensome, and platform-level logging raises surveillance objections that should give any institution pause. I therefore propose an estimation method that requires only two

inputs, both natural to collect: the submitted artifact, and the student's declaration of which model or models they used.

Baseline Differential Analysis proceeds in three steps. First, the assessment system generates a *minimal-effort baseline distribution*: the assignment prompt, submitted verbatim to the declared model several times at standard settings, yielding a sample of what zero-skill utilization produces. Second, the student artifact is compared against this distribution along measurable axes—semantic and structural similarity, specificity of detail, presence of course-specific or locally contextual material the base model cannot know, citation verifiability, argumentative moves absent from the baselines, and stylistic distance. Third, the differential is mapped onto the AUP dimensions to produce not a single score but an evidence profile: for example, “high evidence of iterative refinement and synthesis; weak evidence of verification (two of six citations could not be resolved).”

The logic is inferential, and its epistemic status must be stated honestly. A large, consistent differential is strong evidence of skilled utilization or substantial human contribution—the two are deliberately conflated, since both are what instructors wish to reward. A near-zero differential is strong evidence of minimal-effort use. The method's known failure modes include the brilliant single prompt (skilled compression scored as low iteration), cross-model laundering (declaring one model while using another), and stochastic variance in baselines. These are mitigable—by widening the baseline sample, by testing differentials against several candidate models, and above all by treating BDA output as a *signal for professional judgment* rather than a verdict—but they cannot be eliminated. BDA should therefore be positioned exactly opposite to how detectors were positioned: not as an accusation engine but as a formative instrument, generating feedback students see and can contest, in the spirit of Sadler's (1989) account of formative assessment. The asymmetry matters ethically as well as psychometrically: a false “low proficiency” reading costs rubric points that a student can appeal with process evidence, whereas a false plagiarism accusation costs reputations and, as the detector-bias literature shows, costs them inequitably (Liang et al., 2023).

5.3 Integration into Grading Practice

In practice, AUP enters the grade as a weighted rubric strand alongside disciplinary criteria, with weight varying by course level and outcome. A first-year composition course might weight utilization at ten percent and require a brief “AI methods” statement, mirroring the methods sections of empirical papers. A capstone course might weight it at thirty percent and require students to defend their workflow orally —an authentic analogue of the design reviews and code reviews of professional life.

Mollick and Mollick's (2023) assignment taxonomy supplies ready templates. Two design rules follow from the theory. Weight verification heavily, because it is the dimension on which both learning integrity and epistemic safety depend. And preserve some assessment of unaided fundamentals in secured settings, because verification without knowledge is theater (Lodge et al., 2023).

6. Approach and Method

This is a conceptual and prospective paper, and I want to be explicit about the methods appropriate to that genre. The construct development in Section 5 follows the standard logic of theory-driven framework construction: derive candidate dimensions from established theory (Sections 3.1–3.3), triangulate them against the empirical literature on expert AI use, and specify anchor behaviors at ordinal proficiency levels suitable for rubric translation. The futures claims in Section 7 use structured scenario analysis rather than point prediction: I identify the load-bearing drivers (detector reliability, model capability trajectory, employer demand signals, regulatory posture), state the assumptions under which each phase obtains, and mark the observable indicators that would confirm or disconfirm the trajectory. No new empirical data are collected; the paper's evidentiary base is the published record cited throughout, and its claims are calibrated accordingly—strongest where multiple independent literatures converge (the failure of detection; the productivity effects of skilled use), and explicitly conditional where they concern institutional timelines. Validation of the AUP construct and of Baseline Differential Analysis against ground-truth process data is identified as the priority for subsequent empirical work in Section 9.

7. Three Phases, 2026–2035: A Scenario Analysis

7.1 Phase I — Prohibition Erosion (2026–2028)

In the near phase, detection collapses as a policy instrument faster than official policy admits. Detector procurement quietly lapses; integrity offices, burned by contested false positives, raise their evidentiary thresholds until AI-text cases become practically unprosecutable. Course-level policy fragments—the same student faces prohibition at nine a.m. and mandated AI use at two p.m.—and the incoherence itself becomes the argument for institutional standards. The observable indicators of this phase are already visible in the record: regulator guidance urging redesign over policing (Lodge et al., 2023; UNESCO, 2023), and a first generation of published courses that assign AI use with explicit criteria (Mollick & Mollick, 2023). Early AUP-style rubrics appear as instructor improvisations, typically as a small “process and disclosure” strand.

7.2 Phase II — Hybrid Accommodation (2028–2031)

The middle phase is the institutionalization of a two-lane system. Secured, unaided assessment consolidates around a small core of foundational competencies—the knowledge without which verification is impossible—while the majority of coursework migrates to open-tool conditions with utilization graded explicitly. AI-methods statements become as routine as reference lists. The first commercial and open-source implementations of differential-analysis tooling appear, marketed not as detectors but as feedback engines; accreditation language begins to reference AI literacy as an assessable graduate attribute, following the direction UNESCO (2023) set. The load-bearing assumption of this phase is that model capability continues to improve enough that the baseline for “minimal effort” keeps rising, which continuously widens the gap that skilled utilization must demonstrate—and therefore keeps the construct discriminating. On present trajectories that assumption is conservative.

7.3 Phase III — Proficiency-Centered Assessment (2031–2035)

In the far phase, the inversion completes for knowledge-work disciplines. Submitting work that shows no evidence of skilled AI collaboration reads the way submitting an unreferenced essay reads today: not forbidden, exactly, but self-evidently below professional standard. Orchestration—the sixth dimension—dominates the upper rubric bands as agentic systems make multi-tool workflows the norm rather than the exception. The instructor's role consolidates around the two things the machine cannot supply: setting problems worth solving, and certifying judgment—the student's demonstrated ability to know when the machine is wrong. If there is a single sentence-length summary of the decade, it is that grading migrates from the artifact to the judgment the artifact evidences. The scenario's principal disconfirming indicator would be a sustained plateau in model capability combined with a reliable detection breakthrough; I assess both as unlikely, but the honest position is that Phase III is conditional on Phase II's drivers persisting.

8. Implications for Stakeholders

For instructors, the practical agenda is nearer than the scenario horizon suggests: name utilization quality in rubrics now, require disclosure statements now, and grade the difference between shallow and deep use even informally, because doing so converts an integrity problem into a teaching opportunity (Bearman & Ajjawi, 2023). For institutions, the agenda is coherence—replacing course-by-course improvisation with a graduate-attribute definition of AI proficiency and investing in the secured assessment of fundamentals that makes open-tool assessment defensible. For accreditors and regulators, the lesson of the detector episode is that

policy built on unreliable measurement collapses expensively; utilization-oriented standards should mandate transparency and contestability from the start. For tool builders, the market signal is that the durable product category is not detection but *assessment analytics for augmented work*—systems in the BDA family that generate evidence profiles, surface them to students first, and are audited for the demographic error asymmetries that discredited their predecessors (Liang et al., 2023). And for students, the implication is the least ambiguous of all: the rational strategy under every phase of the scenario is to become demonstrably excellent at working with these systems, because the era in which that excellence was invisible to the grade is ending.

9. Limitations and Ethical Considerations

Four limitations bound the argument. First, the AUP construct is theoretically derived but not yet empirically validated; its dimensions require psychometric work—inter-rater reliability of rubric application, convergent validity against ground-truth process logs gathered from consenting cohorts—before high-stakes use. Second, Baseline Differential Analysis is an inference from output, and every inference of that kind carries irreducible error; the paper's position that BDA outputs must remain formative signals subject to human judgment and student contest is not a caveat but a design requirement. Third, the scenario analysis is conditional on capability and adoption trajectories continuing; scenario methods illuminate structure, they do not guarantee timing. Fourth, there is an equity dimension that inverts rather than disappears: where the detection era penalized students whose prose resembled machine output, a proficiency era risks penalizing students with less access to frontier tools, paid tiers, and the tacit knowledge of skilled use. The remedy is institutional provision—treating access to capable AI as library infrastructure rather than a private purchase—and the explicit teaching of utilization skill rather than the assumption of it. Finally, any system that models student work product must be governed by data-minimization principles: BDA's deliberate refusal to demand conversation logs is an ethical feature, and implementations that quietly expand into surveillance would betray the framework's purpose (Selwyn, 2019; UNESCO, 2023).

10. Conclusion

The detection paradigm asked a question—did the student use AI?—whose answer is becoming simultaneously unknowable and uninteresting. This paper has argued that the question higher education will actually need to answer, and within roughly a decade will routinely grade, is how well the student used it. The argument rests on

converging foundations: assessment theory's demand that we assess authentic performance, distributed cognition's demonstration that human–machine systems are the real unit of cognitive work, and mounting economic evidence that skilled utilization is a high-variance, learnable, valuable capability. The AI Utilization Proficiency framework and Baseline Differential Analysis are offered as a bridge from thesis to practice: a construct instructors can put in a rubric this semester, and a measurement approach that respects both the impossibility of reliable process surveillance and the necessity of honest inference. The universities that make this turn early will not merely have resolved an integrity crisis. They will have noticed, before their competitors, that the thing they exist to certify has changed.
